CLINICAL AND ANTIBACTERIAL ASSESSMENT OF RESIN INFILTRATE VERSUS COMPOMER AS PIT AND FISSURE SEALANTS

Mohamed H. Abo Nahas, Samy Y. El Biomy, Ibrahim F. Barakat

ABSTRACT

Purpose: The aim of the present study was to assess the clinical and antibacterial effectiveness of resin infiltrate versus Compomer as a pit and fissure sealant. Materials and methods: This in-vivo study was carried out on two hundred, young permanent molars of children ranging from six to twelve years of age. The teeth were equally divided into two groups (100 teeth each), based on the sealant material used in sealing the deep pits and fissures. Result: There was significance difference between the antibacterial effect of the Resin infiltration (ICON) and Compomer while there was significant difference between the clinical retention of Resin infiltration (ICON) and Compomer. Conclusion: Compomer has superior antibacterial action against streptococcus mutans than Resin infiltration (ICON). While Resin Infiltration has superior clinical retention than Compomer.

INTRODUCTION

Despite major advances in preventive dentistry in the past decades, dental caries remains one of the most significant oral conditions in young children and is a major cause of dental abscesses and tooth ache.

The main etiological factors associated with dental caries-namely mutants streptococci which includes Streptococcus mutans and streptococcus sorbinus, sugar, and susceptible tooth. Surfaces. There is a clear relationship between dental caries and mutants streptococci. After dental eruption, these microorganisms colonize different tooth surfaces. Fissures form a good reservoir, and even when they are not carious, they harbor mutants streptococci.

The pits and fissures, which forms mechanical retention niches for bacteria, food, and other debris, allow the initiations of enamel demineralization. Preventive measure such as control of bacterial plaque and topical application of fluoride solutions have little effect on these surfaces, more effective measure are therefore necessary, such as the application of occlusal sealants. As a result, the carcinogenic microorganisms present in these fissures lose their viability. It has been suggested that this positive effect could possibly be enhanced by adding fluoride to the sealant material.

Caries infiltration is the new era in the conservative dentistry, The aim of the resin infiltration technique is to allow its penetration by capillarity into the porous enamel, stopping the demineralization process, stabilizing the caries lesion and forming a mechanical barrier, depriving the bacteria that colonize the lesion of the oral biofilm nutrients. Hence, it was been suggested for use as pit and fissure sealant. The capacity of a sealant to prevent dental decay relies directly upon the ability of the sealant material to thoroughly fill pits, fissures, and/or morphological defects and remain completely intact and bonded to enamel surfaces for a life time. The success of fissures sealants depends on the sealant retention, maintenance of integrity and the properties of the sealant materials.
MATERIALS AND METHODS

This in-vivo study was carried out in Pedodontics and Oral Health Department, Faculty of Dentistry, Al-Azhar University, boys, Cairo. Two hundred, young permanent molars of children ranging from six to twelve years of age. The teeth were equally divided into two groups (100 teeth each), based on the sealant material. After polishing the selected tooth with prophy jet and isolation with a rubber dam, the permanent molar of one side delivered ICON® as Resin infiltration and the permanent molar of the other side delivered Compoglass Flow® as Compomer other side. The two materials applied according to the manufacture instructions without modification. After rubber dam removal the child asked to rinse his mouth then the first microbiological sample (baseline) was collected using a sterile intraoral swab from the buccal and occlusal surface. The sample preserved in a sterile screw capped tube containing 9 ml Thioglycolate broth media and transferred to the microbiological laboratory to be cultured on Mitissalivaris agar and bacterial counting. After one month the child asked not to brush his teeth in the day of sampling then the second sample was collected from the sealant surface using the sterile cotton, then after three months the same steps were done collecting the third sample.

Clinical evaluations were done 3 and 6 months after sealant application. The following criteria will be adopted to evaluate the retention of the sealant (9). Total Retention (TR) : total retention of sealant on the occlusal surface; Partial Retention Type 1 (PR1): presence of sealant in 2/3 of the pit extension, with small fractures and losses of material, Partial Retention Type 2 (PR2): presence of sealant in 1/3 of the pit extension with fractures and losses of material, Total Loss (TL) : absence of sealant on the occlusal surface.

Data were tabulated in Excel worksheets, and statistical analysis was performed with SPSS (Chi., IL, USA) software. Descriptive statistics were presented as mean ± standard deviation for each group of primary anterior teeth. The results were analyzed using Student’s t-test, and significant differences were defined as P < 0.05.

RESULTS

For ICON group there was a statistically significant decrease in S. mutans count after one month and no statistically significant after three months. For Compomer group there was no statistically difference of S. mutans count after one month and after three months. After one month there was a statistically significant difference between ICON and Compomer where p=0.01. The highest mean value was found in ICON group while the least mean value was found in Compomer. After three months there was a statistically significant difference between ICON group and Compomer group where p=0.01. The highest mean value was found in ICON while the least mean value was found in Compomer (Table 1 & Fig. 1).

**DISCUSSION**

In the current study, the rate of increase in SM counts was compared in both groups over time. Non-significant difference was found in the rate of increase of SM among the compomer group. This might be attributed to the antibacterial activity of fluoride released from compomer in dental plaque and in agreement with Pinar who found that Fluoride concentrations in plaque can exert inhibitory effects on oral microflora growth\(^{(10)}\). Where van Loveren, in his in vitro experiments have demonstrated that the acid production of S.M. and lactobacilli was reduced in layers overlying fluoridated enamel\(^{(11)}\).

On the other hand, significant difference was found between the compomer group and ICON group. After one month. This difference is in agreement with Arslan in vitro study comparing the bacterial adhesion and count adjacent to ICON and Enamel Pro Varnish\(^{(12)}\). The same conclusion existed in Hallgren et al. who found significantly higher fluoride concentration and lower level of S.M adjacent to glass ionomer compare to that adjacent to resin composite and concluded that the use of glass ionomer creates a local ecological condition that affects the establishment of S.M, thus a less caries inducing micro flora may develop.
Although, a significant difference of the S.M count in both groups after one month was existed but it was much less in value in comparable to that found in Hallgren et al. study. This may be contributed to that this study is designed with the concept of split mouth technique, which permits the crossover of fluoride from compomer segment to ICON segment\(^{(13)}\).

These results were in disagreement with Wright et al., Hong et al and Mota et al. who found no significant difference in plaque adjacent to glass ionomer compared to composite resin\(^{(14-16)}\). This may be contributed to that; their experiments were about the use of hybrid glass ionomer and composite resin as bonding material for the brackets of fixed orthodontic appliance using the split mouth technique which cause more crossover of fluoride from hybrid glass ionomer segment to the composite segment. This might be the cause of non-significant difference between the two materials and reduce the power of the experiment to find a difference as stated by Benson et al\(^{(13)}\).

Moreover, after three months, S.M counts increase in plaque adjacent to ICON more than the S.M counts increase in the plaque adjacent to compomer. This result was found to be statistically significant and was also in agreement with the study conducted by Soly et al., fluoride varnish was more effective in reducing bacterial adhesion compared with resin infiltrate (ICON)\(^{(12)}\).

In the current study, the Clinical results showed a significant difference between Compoglass flow and ICON regarding the total retention, partial retention and total loss along the 3 and 6 months follow up periods, this explain the superior retention capability of infiltration as a fissure sealant over Polyacid-modified resin-based fissure sealants (Compomer), and this comes in agreement with Yakut et al. who compared resin sealant vs. polyacid-modified resin composite in two year clinical study\(^{(17)}\). and in disaggreement with Puppin-Rontan et al study who found no signifcant difference regarding total retention of both Compoglass flow versus Flouroshielded which is resin based sealant, after two years study\(^{(4)}\).

**CONCLUSION**

Compomer (Compoglass flow) has superior antibacterial effect against streptococcus mutans superior to resin infiltration (ICON). While Resin infiltration (ICON) has a better clinical retention as a fissure sealant than Compomer (Compoglass flow).

**RECOMMENDATIONS**

It is recommended to investigate the bacterial adhesion on ICON compared to one of other non-fluoride releasing resin-based fissure sealant without using split mouth technique. Also, Longer period of follow up is needed to test the clinical retention of resin infiltration system (ICON\(^{®}\)) as a fissure sealant.
